Abstract Power management is becoming an increasingly critical component of modern enterprise computing environments. The traditional drive for higher performance has influenced trends towards consolidation and higher densities, artifacts enabled by virtualization and new small form factor server blades. The resulting effect has been increased power and cooling requirements in data centers which elevate ownership costs and put more pressure on rack and enclosure densities. To address these issues, we exploit a fundamental characteristic of data centers: “platform heterogeneity”. This heterogeneity stems from the architectural and management-capability variations of the underlying platforms. We define an intelligent heterogeneity-aware load management (HALM) system that leverages heterogeneity characteristics to provide two data center level benefits: (i) power efficient allocations of workloads to the best fitting platforms and (ii) improved overall performance in a power constrained environment. Our infrastructure relies upon platform and workload descriptors as well as a novel analytical prediction layer that accurately predicts workload power/performance across different platform architectures and power management capabilities. Our allocation scheme

achieves on average 20% improvements in power efficiency for representative heterogeneous data center configurations, and up to 18% improvements in performance degradation when power budgeting must be performed. These results highlight the significant potential of heterogeneity-aware management.

Keywords Power management · Distributed resource management · Heterogeneous systems

1 Introduction

Power management has become a critical component of modern computing systems, pervading both mobile and enterprise environments. Power consumption is a particularly significant issue in data centers, stimulating a variety of research for server systems [2]. Increased performance requirements in data centers have resulted in elevated densities enabled via consolidation and reduced server form factors. This has in turn created challenges in provisioning the necessary power and cooling capacities. For example, current data centers allocate nearly 60 Amps per rack, a limit that is likely to become prohibitive for future high density rack configurations such as blade servers, even if the accompanying cooling issues can be solved [24]. In addition, a 30,000 square feet data center with a power consumption of 10 MW requires a cooling system which costs \$2–\$5 million [21]. In such a system, the cost of running the air conditioning equipment alone can reach \$4–\$8 million a year [24]. Coupled with the elevated electricity costs from high performance servers, these effects can substantially affect the operating costs of a data center. Overall, these trends in power/cooling delivery and cost highlight the need for power and thermal management support in data centers.

109 Previous work on server management has focused on
 110 managing heat during thermal events [21] or utilizing plat-
 111 form power management support, such as processor fre-
 112 quency scaling, for power budgeting [9, 18, 24]. In this pa-
 113 per, we approach the problem of managing data centers from
 114 a different perspective by considering how to intelligently
 115 allocate workloads amongst heterogeneous platforms in a
 116 manner that (i) improves data center power-efficiency while
 117 preserving/satisfying workload performance requirements,
 118 and (ii) meets data-center-level power budgets with minimal
 119 impact on workload performance. Typically, data centers
 120 statically allocate platform resources to applications based
 121 upon peak load characteristics in order to maintain isola-
 122 tion and provide performance guarantees. With the continu-
 123 ing growth in capabilities of virtualization solutions (e.g.,
 124 Xen [1] and VMware [25]), the necessity of such offline
 125 provisioning is removed. Indeed, by allowing for flexible
 126 and dynamic migration of workloads across physical re-
 127 sources [6], the use of virtualization in future data centers
 128 enables a new avenue of management and optimization. Our
 129 approach begins to leverage some of these capabilities to
 130 enhance power efficiency by taking advantage of the ability
 131 to assign virtualized applications to varying sets of underly-
 132 ing hardware platforms based upon performance needs and
 133 power consumption characteristics.

134 Throughout their lifetimes, data centers continually up-
 135 grade servers due to failures, capacity increases, and mi-
 136 grations to new form factors [12]. Over time, this leads to
 137 data centers comprised of a range of heterogeneous plat-
 138 forms with differences in component technologies; power,
 139 performance and thermal characteristics; and power man-
 140 agement capabilities. When provisioning resources to work-
 141 loads in these heterogeneous environments, power efficiency
 142 can vary significantly based on the particular allocation. For
 143 example, by assigning a memory bound workload to a plat-
 144 form that can perform dynamic voltage and frequency scal-
 145 ing (DVFS), run-time power consumption can be reduced
 146 with minimal impact to performance [19]. We propose a
 147 novel heterogeneity-aware load management (HALM) ar-
 148 chitecture to achieve this power-friendly behavior in data
 149 centers.
 150

151 Allocating power and cooling resources is another sig-
 152 nificant challenge in the modern data center. Though clearly
 153 beneficial for transient power delivery and cooling issues,
 154 power budgeting solutions can also be useful in the provi-
 155 sioning of these resources. Traditionally, power and cooling
 156 have been allocated based on the nameplate rating of the sys-
 157 tem power supply or its maximum output power. However, a
 158 fully utilized server with a typical configuration will see its
 159 electrical load between 60%–75% of the name plate rating
 160 with most enterprise workloads. Therefore, providing power
 161 and cooling capacity based on these worst case assumptions
 162

163 results in either over allocation of power and cooling ca-
 164 pacity or underutilization of server rack space leading to in-
 165 creased capital costs and underutilized data centers. Allocat-
 166 ing power and cooling capacity based on the average work-
 167 load behavior within a server and across a data center allows
 168 significantly increased densities but requires dynamic pro-
 169 tection mechanisms that can limit server power consump-
 170 tion when demand temporarily exceeds available capacity.
 171 These mechanisms have been recently proposed in the litera-
 172 ture and explored in the industry [8]. While very effective
 173 in limiting power and protecting the infrastructure, they may
 174 result in nontrivial degradation of peak performance, espe-
 175 cially when the power constraint is too prohibitive. In this
 176 paper we illustrate how HALM can lessen the performance
 177 impact of data center power budgeting strategies.

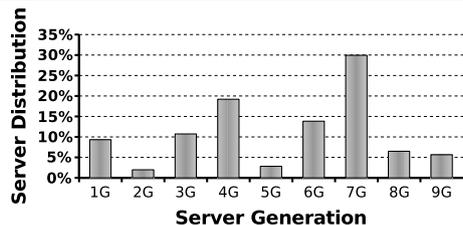

178 Intelligent mapping of applications to underlying plat-
 179 forms is dependent upon the availability of relevant infor-
 180 mation about workloads and hardware resources. As part of
 181 HALM, we extend the use of *workload* and *platform de-*
 182 *scriptors* for this purpose, which are then used by a *pre-*
 183 *dictor* component that estimates the achievable performance
 184 and power savings across the different platforms in the data
 185 center. These predictions are finally used by an *allocation*
 186 *layer* that map workloads to a specific type of platform. This
 187 overall infrastructure is evaluated using data center con-
 188 figurations consisting of variations upon four distinct plat-
 189 forms. In summary, the main contributions of our HALM
 190 system are: (i) a platform heterogeneity-aware power man-
 191 agement infrastructure that improves data center power effi-
 192 ciency under workload performance constraints and limited
 193 data center power budgets; (ii) an allocation infrastructure
 194 that uses workload and platform descriptors to perform map-
 195 pings of hardware to virtualized workloads; and (iii) an in-
 196 telligent load shedding policy to dynamically meet transient
 197 changes in power consumption limits. Evaluations of our
 198 system performed on state-of-the art platforms, including
 199 Intel® Core™ microarchitecture based hardware, demon-
 200 strate the benefits of exploiting platform heterogeneity for
 201 power management.
 202

2 Motivation 203

2.1 Data center composition and exploiting heterogeneity 204

205 Data center deployments are inherently heterogeneous. Up-
 206 grade cycles and replacement of failed components and
 207 systems contribute to this heterogeneity. In addition, new
 208 processor and memory architectures appear every few years,
 209 and reliability requirements are becoming ever more strin-
 210 gent. The effect of these trends is reflected by a recent sur-
 211 vey of data center managers that found that 90% of the facil-
 212 ities are expected to upgrade their compute and storage in-
 213 frastructure in the next two years. Figure 1(a) shows a distri-
 214 bution of different systems in a representative enterprise data
 215 center.
 216

Cluster Comput

(a) Data Center Composition

	System A		System B	
	W1	W2	W1	W2
CPU Power	90W	40W	90W	20W
System Power	160W	120W	160W	120W
PSU Efficiency	86%	70%	87%	80%
Total Power	291W	229W	287W	175W

(b) Heterogeneity Management Example

Fig. 1 Data center heterogeneity and management benefits

center. As the figure shows, the data center contains nine different generations of systems that have either (1) different processor architectures, cores and frequencies; (2) varying memory capacity and interconnect speeds; or (3) different I/O capabilities. While all systems support the same software stack, they have very different and often asymmetric performance and power characteristics.

Traditionally, the non-uniformity of systems in a data center has been characterized by different levels of performance and power consumption. However, recently, another dimension has been added to this heterogeneity because server platforms are beginning to offer rich thermal and power management capabilities. Processors support DVFS and aggressive sleep states to conserve CPU power. New memory power management implementations allow different DRAM devices to go to lower power states when inactive, and enable bandwidth throttling for thermal protection. Server power supplies exhibit different conversion efficiencies under different loads, directly impacting the overall power efficiency of the system. Since power efficiency has become an important thrust in enterprise systems, we expect component and platform vendors to continue introducing new power and thermal management capabilities into their products, including I/O and system buses, chipsets, and network and disk interfaces, making future platforms even more heterogeneous.

Previous work has proposed different approaches for energy-efficient workload allocation in clusters, but none have accounted for system level power management and thermal characteristics. Therefore, the workload allocations proposed by previous approaches will yield less than ideal results since they are completely unaware of power and thermal management effects on system performance and power consumption. To illustrate this phenomenon, we experimentally compare two dual processor systems, *A* and *B*, running two different workloads, as shown in Fig. 1(b). The differences between the two systems are in the power supply unit (PSU) and processor power management capabilities. System *A* has a less efficient power supply at light load and has processors with limited power management support. System *B*, on the other hand, has a high efficiency power supply across all loads and processors that support a rich set

of power management capabilities. We measure power consumption on these platforms using two different synthetic workloads: one with full utilization (*W1*) and one with a very low level of utilization (*W2*). *W1* consumes about the same amount of power on both platforms. However, allocating the low-utilization *W2* to system *A* leads to very power inefficient execution. Since *A* does not support power management and has low PSU efficiency at light load, its total system power is more than 50 W higher than that of system *B*. Thus, while both systems meet the performance demand of both workloads, heterogeneity-aware resource allocation can decrease total power by more than 10%, translating into millions of dollars in savings for large data centers. As this example shows, a full knowledge of system power and supported power management features is required to efficiently allocate workloads. Our HALM system is designed to provide such functionality.

2.2 Benefits of heterogeneity-aware management

To further motivate the need and benefits of heterogeneity-aware management in data centers, we perform two opportunity studies. The first study considers the possible benefits of allocating workloads by matching system capabilities and workload execution characteristics to reduce a data center’s power profile while also meeting workload performance demands. We analyze an example of running a set of workloads in a data center configuration with four unique types of platforms described later in the paper, each with different power/performance characteristics. The set of workloads includes ten computational benchmarks (*swim*, *bzip2*, *mesa*, *gcc*, *mcf*, *art*, *applu*, *vortex*, *sixtrack*, and *lucas* from SPEC CPU2000) and one transaction-oriented workload (SPECjbb2005). We generate all subsets of four from these eleven benchmarks and compare three allocation policies for each of the subsets in Fig. 2(a). The ‘worst case’ allocation distributes the benchmarks across platforms to maximize power consumption, ‘random’ allocates workloads to platforms randomly, and ‘optimal’ distributes the workloads to minimize power consumption. For each workload, we allocate as many systems of a given type as necessary to meet workload throughput requirements. Subsets

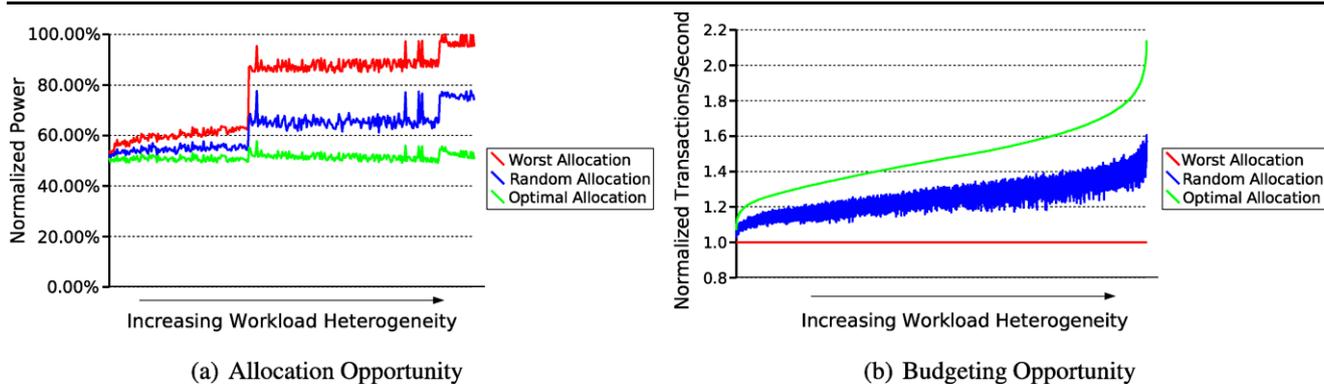

Fig. 2 Opportunity analysis of heterogeneity-aware management

that have benchmarks with more homogeneous behavior, i.e. similar processor and memory usage behavior, appear on the left side of the graph, while subsets with more heterogeneous benchmarks appear on the right. As can be seen from the figure, subsets of workloads with more heterogeneous behavior can substantially benefit from heterogeneity-aware resource allocation. Averaging across all subsets, the optimal policy can reduce total power by 18% when compared to random allocation and by 34% over worst-case allocation, without compromising workload performance.

The second opportunity study considers how the aggregate throughput of a set of workloads varies within a given power budget based upon allocations. In particular, we assume that we have one of each of our four unique platforms and again generate subsets of four workloads from a set of SPEC CPU2000 benchmarks. For each subset, we calculate the minimum, average, and best case throughput across all permutations of possible allocations of the four workloads onto the four platforms. Figure 2(b) provides the results, where each scenario is normalized by the minimum throughput value to provide fair comparisons. We find that on average, the best case allocation provides a 23% improvement in performance over the random allocation, and a 48% improvement compared to the worst-case. These results highlight the relationship between allocation decisions and performance when a power budget must be imposed.

Summarizing, HALM addresses the power benefits of heterogeneity-aware allocation for two cases: (1) when there is no power budget and (2) when such a budget must be imposed temporarily due to power delivery or cooling constraints or as part of a power provisioning strategy [8].

3 Scalable enterprise and data center management

Our previous discussions have motivated the need to augment the behavior of data centers to improve manageability by leveraging the heterogeneity in platform capabilities.

HALM extends this support with its heterogeneity-aware workload allocation infrastructure that utilizes the flexibility of rapidly developing virtualization technologies. Virtualization attempts to provide capabilities and abstractions that significantly impact the landscape of enterprise management. For example, there is active work to ensure performance isolation benefits, where it will be possible to run multiple virtual machines (VMs) within a given physical platform without interference among applications [15]. Currently, VMs can coexist on a platform with negligible performance interference as long as resources are not over-committed. Approaches that allow for resource pools and reservations as well as dynamic resource sharing and reclamation can aid in providing isolation even when systems are over-provisioned. Secondly, by encapsulating application state within well defined virtual machines, migration of workloads among resources can be performed easily and efficiently. A more powerful contribution of virtualization, however, is the ability to combine multiple resources across physical boundaries to create virtual platforms for applications, providing a *scalable enterprise* environment. HALM assumes the existence of this flexible and powerful virtualization support.

The usage pattern of data centers is becoming increasingly service-oriented, where applications and workloads may be submitted dynamically by subscribers/clients. When managing these types of applications certain management actions, such as allocation decisions, happen at a coarse granularity with finer adjustments being made at runtime to address transient issues such as reduced power budgets. One can imagine how such a data center might be managed with the typically used assignment approaches. At some infrequent interval the pool of applications and service level agreements (SLAs) that specify their required performance, in metrics such as throughput or response time, are compiled. Applications are then assigned to platforms using a simple load balancing scheme based upon utilization or queue lengths, possibly even accounting for differences in the performance of the systems [26], so that SLAs are met.

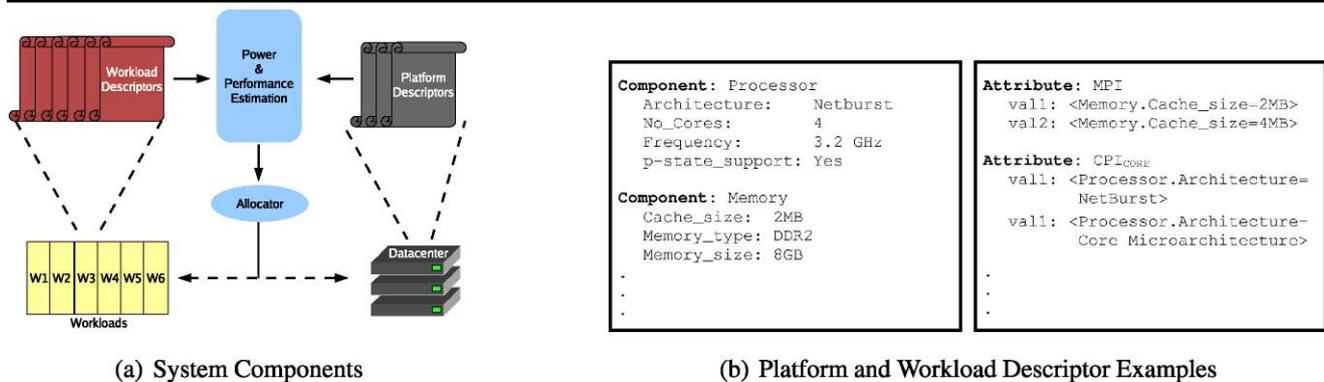

Fig. 3 HALM architecture

When load must be reduced to address power budgeting requirements, load might be shed from workloads in a similarly random or round robin fashion. This approach clearly leaves room for improvement, since it does not consider power or platform differences in any way. HALM addresses this weakness by performing heterogeneity aware allocations as well as intelligent load shedding.

The HALM architecture can be organized into three major components: (1) platform/workload descriptors, (2) a power/performance predictor, and (3) an allocator, as shown in Fig. 3(a). We use platform and workload descriptors to provide our workload allocator with the differences amongst workloads and platforms. These descriptor inputs are utilized by the predictor to determine: (1) the relative performance of workloads on different types of platforms, and (2) the power savings achievable from platform power management mechanisms. Coupled with coarse platform power consumption information (obtained via online power monitoring) (3) the allocator, performs the assignments of workloads to the available resources.

The purpose of platform descriptors is to convey information regarding the hardware and power management capabilities of a machine. A platform descriptor is made up of multiple modules, representing different system components, as shown in Fig. 3(b). Each module specifies the type of component to which it refers, such as processor, memory subsystem, or power supply. Within each of these modules, various component parameters are defined. For example, a module describing the processor component may have attributes like its microarchitecture family, frequency, and available management support. Workload descriptors are also structured in modules, headed with attribute declarations. Within each module, a list of values for that attribute is provided. As workload attributes often vary with the platforms on which it executes, our descriptor design allows multiple attribute definitions, where each definition is predicated with component parameter values that correlate back to platform descriptors. Figure 3(b) illustrates the structure of the resulting workload descriptor. We further explain the meaning of the

MPI (memory accesses per instruction) and CPICORE (core cycles per instruction) attributes in subsequent sections.

Platform descriptor information can be provided in a variety of ways. It can be made readily available using platform support such as ACPI [13], and possibly also with some administrative input. To provide the required workload descriptors, we profile workloads on a minimal set of *orthogonal platforms*, with mutually exclusive component types. We then use an analytical prediction approach to project workload characteristics on all available platforms. As we discuss in Sect. 5, this approach provides accurate predictions that scale with increased amounts of heterogeneity.

4 Methodology

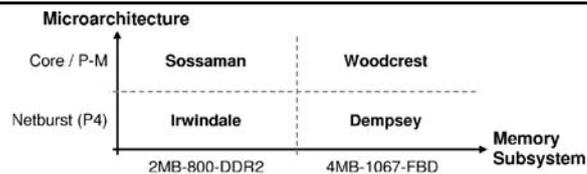

4.1 Platform hardware

Our hardware setup consists of four types of rack mounted server platforms summarized in Fig. 4(a), where LLC denotes last-level cache size. All four types of platforms contain standard components and typical configurations that entered production cycles. In our experiments Linux was installed on all systems for measurement of various attributes (e.g. CPI, MPI, etc.) as well as performance. We validated that the performance results matched those with Xen using a subset of workloads and platforms, but performed the majority of our experiments in a non-virtualized environment to have better access to performance counters used to measure other workload attributes.

The platform names are based on their processor code name in this paper. All four platforms are dual-processor systems. Woodcrest, Sossaman, and Dempsey are CMP dual-core processors, and Irwindale is a 2-way SMT processor supporting Hyper-Threading Technology. All platforms have 8 GB of memory. Woodcrest and Dempsey support Fully Buffered DIMM (FBD) memory with a 533 MHz DDR2 bus, while Sossaman and Irwindale support unregistered DDR2 400 MHz memory. Woodcrest and Dempsey

					2.8	X	X	13

have dual FSB architectures with two branches to memory and two channels per branch.

All four types of systems are heterogeneous in a sense that each has a unique combination of processor architecture and memory subsystem. If we assume that Intel Core microarchitecture/Pentium® M and NetBurst constitute two types of processors and LLC-4 MB/FSB-1066/FBD-533 and LLC-2 MB/FSB-800/DDR2-400 constitute two types of memory, all four platforms can be mapped as having unique processor/memory architecture combinations. Note that all four platforms also have vastly different power and performance characteristics. For example, the Intel Core microar-

chitecture is superior to NetBurst both in terms of performance and power efficiency. FBD based memory, on the other hand, provides higher throughput in our systems at the expense of elevated power consumption due to increased DDR2 bus speed and the power requirements of the Advanced Memory Buffer (AMB) on the buffered DIMMs. The four platforms occupy separate quadrants of a heterogeneity space with dimensions of microarchitecture heterogeneity and memory subsystem heterogeneity, as shown in Fig. 4(b). We refer to this initial level of heterogeneity as “across-platform heterogeneity”. However, in addition to this, all these server platforms also support chip-level DVFS.

This leads to a second degree of heterogeneity, where one type of platform can have instances in a data center that are configured to operate at different frequencies. We refer to this as “*within-platform heterogeneity*”. As process variations increasingly result in the *binning* of produced chips into different operating points, this within-platform heterogeneity becomes an inherent property of the general data center landscape. Finally, many of these platforms may incorporate some processor dynamic power management (DPM) techniques that adaptively alter platform behavior at runtime. This creates a third source of heterogeneity, “*DPM-capability heterogeneity*”, where platforms with built-in DPM hooks exhibit different power/performance characteristics from the ones with no DPM capabilities. In Table 1, we show how these three levels of heterogeneity quickly escalate the number of distinct platform configurations in a data center scenario.

All experimental power measurements are performed using the Extech 380801 power analyzer. The power is measured at the wall and represents total AC power consumption of the entire system. The power numbers presented in this paper are obtained by averaging the instantaneous system power consumption over the entire run of each workload. Our assumption is that infrastructure support for monitoring power consumption will be utilized to obtain this type of workload specific power characteristics online, instead of parameterized models. For example, all power supplies, which adhere to the latest power supply monitoring interface (PSMI) specification, support out-of-band current/voltage sampling allowing for per platform A/C power monitoring reflected by our actual power measurements.

4.2 Application model

When power managing computing environments, improvements can be attained with a variety of approaches. In this work, we consider two scenarios. The first assumes a lack of budgeting constraints, concentrating on a workload allocation that reduces power consumption while maintaining baseline application performance. In other words, we maximize the performance per watt, while holding performance constant. The second addresses power budgeting by performing load shedding to reduce power consumption while minimizing performance impact to workloads. We consider application performance in terms of throughput, or the rate at which transaction operations are performed. Therefore, it is not the execution time of each transaction that defines performance, but the rate at which multiple transactions can be sustained. This type of model is representative of applications such as transaction based web services or payroll systems.

The goal of HALM is to evaluate the power-efficiency tradeoffs of assigning a workload to a variety of platforms.

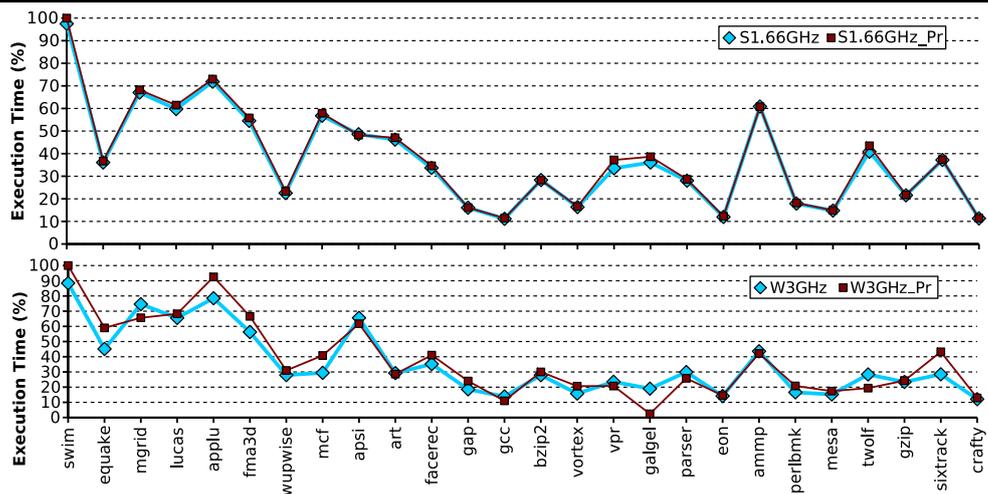

Since the performance capabilities of each platform are different, the execution time to perform a single operable unit, or atomic transaction, varies across them. As previously mentioned, virtualization technologies can help to extend the physical resources dedicated to applications when necessary to maintain performance by increasing the number of platforms used to execute transactions. In particular, transactions can be distributed amongst nodes until the desired throughput is reached.

For our analysis, we consider applications that mimic the high performance computational applications common to data center environments and also heavily exercise the power hungry components of server platforms, the processor and memory. Two aspects of these workloads are captured in our experimental analysis. First, these workloads are inherently transactional, such as the previous financial payroll example or the processing of risk analysis models across different inputs common to investment banking. Second, with the ability to incorporate large amounts of memory into platforms at relatively low costs, these applications often execute mostly from memory, with little or no I/O being performed. Though I/O such as network use can play a significant role in multi-tier enterprise applications, we leave consideration of such characteristics to future work. To realize our application model, while also providing deterministic and repeatable behavior for our experimentation, we utilize benchmarks from the SPEC CPU2000 suite as representative examples of transaction instances. SPEC benchmarks allow for the isolation of processor and memory components, while also generating different memory loads. Indeed, many SPEC benchmarks exhibit significant measured memory bandwidth of 5–8 GB/sec on our systems. In order to provide an unbiased workload set, we include all SPEC benchmarks in our experiments. For each application, we specify an SLA in terms of required transaction processing rate, equal to the throughput achievable on the Woodcrest platform.

5 Workload behavior estimation

The power/performance predictor component of our HALM framework can be implemented in multiple ways. For example, one can profile a set of microbenchmarks on all platform configurations and develop statistical mapping functions across these configurations. However, as the platform types and heterogeneity increase, the overhead of such approaches can be prohibitive. Instead, we develop a predictor that relies on the architectural platform properties and adjusts its predictions based on the heterogeneity specifications. We refer to this model as the “*Blocking Factor (BF) Model*”. The BF model simply decomposes execution cycles into *CPU cycles* and *memory cycles*. CPU cycles represent

Fig. 5 Performance prediction results

the execution with a perfect last-level cache (LLC), while memory cycles capture the finite cache effects. This model is similar to the “*overlap model*” described by Chou et al. [5]. With the BF model, the CPI (cycles per instruction) of a workload can be represented as in (1). Here CPI_{CORE} represents the CPI with a perfect LLC. This term is independent from the underlying memory subsystem. CPI_{MEM} accounts for the additional cycles spent for memory accesses with a finite-sized cache:

$$CPI = CPI_{CORE} + CPI_{MEM}. \quad (1)$$

The CPI_{MEM} term can be expanded into architecture and workload specific characteristics. Based on this, the CPI of a platform at a specific frequency f_1 can be expressed as in (2). Here, MPI is the memory accesses per instruction, which is dependent on the workload and the LLC size, L is the average memory latency, which varies based upon the memory subsystem specifications, and BF is the *blocking factor* that accounts for the overlapping concurrent execution during memory accesses, which is a characteristic of the workload:

$$CPI(f_1) = CPI_{CORE}(f_1) + MPI \cdot L(f_1) \cdot BF(f_1). \quad (2)$$

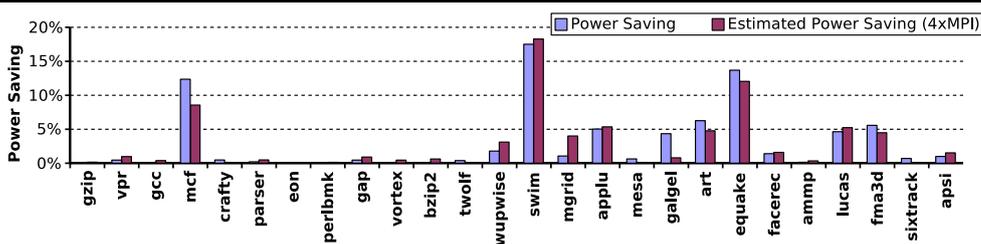

Using variants of (2), performance prediction can be performed relatively easily for within-platform heterogeneity, as well as across-platform heterogeneity. For within-platform heterogeneity, the frequency-dependent components of (2) are scaled with frequency to predict workload performance on a different frequency setting. The top chart in Fig. 5 provides results for an example of this type of prediction with an orthogonal platform (Sossaman). The figure contains the actual measured performance for our workloads together with the predicted performance.

In the latter case of across-platform heterogeneity, the natural decoupling of the microarchitectural and memory

subsystem differences in the BF model enables us to estimate application performance on a platform lying on a different corner of the memory and microarchitecture heterogeneity space. Among our four experimental platforms, two “*orthogonal platforms*”, which span two opposite corners of the platform heterogeneity quadrants in Fig. 4(b), can be used to predict performance on a third “*derived platform*”. The lower chart in Fig. 5 shows the prediction results for the Woodcrest platform, whose performance is “*derived*” using the CPI_{CORE} and CPI_{MEM} characteristics of the orthogonal platforms (Sossaman and Dempsey respectively). Overall, for the orthogonal platforms, the BF model can very accurately predict performance with an average prediction error of 2%. For the derived platforms, our predictor can track actual execution times very well, though with an increased average prediction error of 20%. In the following sections, we show that this performance prediction methodology provides sufficient accuracy to represent workload behavior and allows HALM to achieve close to optimal allocations. Further details of this prediction methodology can be found in our previous work [22].

The final heterogeneity type supported by our predictor is the DPM-capability heterogeneity. For this, we consider a platform that enables DVFS during memory bound execution regions of an application. We implement this functionality as part of OS power management, based on prior work [14]. To incorporate DPM awareness, we extend the predictor component to estimate the potential power savings that can be attained when executing a workload on a DPM enabled platform. Experimental results show that there is a strong correlation between the MPI of a workload and its power saving potential. Therefore, we utilize the MPI attribute in the workload descriptors to predict the power saving potentials of workloads on DPM enabled platforms. Figure 6 shows that our MPI based prediction approach effectively captures the power saving potentials of different workloads and successfully differentiates applications that

Fig. 6 Power saving predictions for DPM enabled platforms

can benefit significantly from being allocated to a DPM enabled machine. As we describe in Sect. 6.1, we use this predictor to choose workloads that should be assigned to the DPM enabled platforms.

6 Management policies

6.1 HALM allocation policy

After processing the workload and platform descriptors, and utilizing our BF model for performance prediction, the next step is to perform allocation of resources to a set of applications in a data center. Evaluations are based on a greedy policy for allocating workloads. In particular, with each application i , we associate a cost metric for executing on each platform type k . Workloads are then ordered into a scheduling queue based on their maximum cost metric across all platform types. The allocator then performs application assignment based on this queue, where applications with higher worst-case costs have priority. The platform type chosen for an application is a function of this cost metric across the available platforms as well as the estimated DPM benefits. As a cost metric for our policy, we define $N_{i,k}$, the number of platforms of type k required to execute a workload i , $N_{i,k}$. This value is clearly a function of both the performance capabilities of the platform and the SLA requirement of the workload. $N_{i,k}$ can be analytically defined, given the transaction based application model utilized in our work. For each application i , the service level agreement (SLA) specifies that X_i transactions should be performed every Y_i time units. If $t_{i,k}$ is the execution time of a transaction of application i on platform k , the resulting number of platforms required to achieve the SLA can be expressed with (3)

$$N_{i,k} = \left\lceil \frac{X_i}{\lfloor Y_i/t_{i,k} \rfloor} \right\rceil. \tag{3}$$

The $t_{i,k}$ values are provided by the performance predictor. It should be noted that there is a discretization in $N_{i,k}$, which is due to the fact that individual atomic transactions cannot be parallelized across multiple platforms. $N_{i,k}$ is therefore better able to handle errors due to the inherent discretization performed, making it a strong choice as a cost metric

(other possible metrics are discussed and defined in our previous work [22]). Given the use of $N_{i,k}$ as our cost metric, our allocation approach first determines the platform types of which (1) there are enough available systems to allocate the workload and (2) the cost metric is minimized. We then use DPM savings to determine whether a more power efficient platform alternative should be used between those with the same cost value. In other words, if there are multiple platform types for which an application has the same $N_{i,k}$ value, we utilize a DPM specific threshold to decide whether or not it should be scheduled to a DPM enabled platform type. As we demonstrate in the following section, this threshold based approach can be effective in identifying workloads that can take advantage of DPM capabilities.

6.2 HALM power budgeting policy

In order to address transient power delivery or cooling issues, it is sometimes necessary to temporarily reduce power consumption in a data center. To provide this mechanism, we develop a load shedding policy based upon an existing workload allocation scheme. The goal of the policy is to reduce the amount of resources provided to applications in order to meet a power budget while still allowing all workloads to make some progress. In other words, application performance may be degraded compared to prescribed SLAs, but all applications achieve some fraction of their SLA.

Our power budgeting policy is, again, a greedy approach. For all applications with resources that can be shed, i.e. applications that utilize more than one platform, we define a power-efficiency metric as the throughput per Watt that is being provided by each resource. Afterwards, the resources with minimal power efficiency are shed until the power budget is met. As our experimental results demonstrate, this simple metric allows for improved performance when power budgeting must be performed, as well as better fairness across workloads in terms of performance degradation experienced.

7 Experimental evaluation

7.1 Increasing power efficiency

In order to evaluate our heterogeneity-aware allocation approach, we perform power and performance measurements

973 of our SPEC based representative transactional workloads
 974 across each type of platform. To scale these results to the
 975 number of platforms present in data centers, this measured
 976 data is extrapolated analytically using a data center allocation
 977 simulator which combines real power and performance
 978 data, prediction output, and allocation policy definitions to
 979 calculate power efficiency in various data center configura-
 980 tions. In the simulator, we provide the output of the predictor
 981 as input to the allocation policy. We always assume that the
 982 platforms which are profiled are the 2 GHz Sossaman plat-
 983 form and the 3.7 GHz Dempsey system. Since we assume
 984 the workload attributes are profiled accurately on these sys-
 985 tems, for fairness we also assume that for these two plat-
 986 forms performance data is obtained via profiling as well and
 987 is therefore known perfectly. We then consider three differ-
 988 ent scenarios: (1) all other platform performance informa-
 989 tion is known perfectly (oracle) (2) our BF model is used to
 990 predict performance for the remainder of platforms as de-
 991 scribed in Sect. 5 (BF model) (3) incorporating a simple sta-
 992 tistical regression approach (Stat. Est.). For this regression
 993 method, we profile a subset of applications across all plat-
 994 forms to obtain linear performance prediction models para-
 995 meterized by variables that can be obtained by profiling a
 996 workload on the 2 GHz Sossaman and 3.7 GHz Dempsey
 997 systems (CPI, MPI, etc.). The regression models can then
 998 be used to predict performance of any application. The base-
 999 line allocation scheme we compare against is a random one,
 1000 since it closely estimates the common round-robin or uti-
 1001 lization based approach.

1002 The efficiency improvements achievable in a data center
 1003 are also dependent upon the system’s current mix of appli-
 1004 cations. To obtain our results, we randomly pick applica-
 1005 tions and allocate them using the random approach until no
 1006 more workloads can be scheduled. Using the resulting set
 1007 of workloads, we then evaluate power consumption when
 1008 using our prediction and allocation policies, and compare
 1009 them against the random allocation result. This is repeated a
 1010 hundred times for each of our data points.

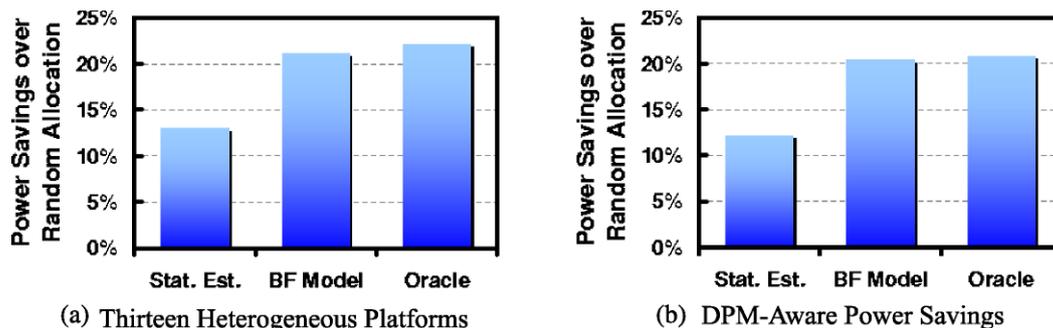

1011 We first look at the benefits achieved with HALM in
 1012 data center configurations with across-platform and within-

1027 platform heterogeneity but no DPM support. In particular,
 1028 we include the four base platforms, Woodcrest, Sossaman,
 1029 Dempsey, and Irwindale, as well as the frequency variations
 1030 of the platforms. We create data center configurations with
 1031 equal numbers of each type of system. Trends are consistent
 1032 across various data center sizes, so for brevity, we include
 1033 here only results with 1000 platforms of each type. The re-
 1034 sulting data center has 13 types of platforms, and power con-
 1035 sumptions vary with allocation as shown in Fig. 7(a). The
 1036 first interesting observation is that platform heterogeneity al-
 1037 lows us to achieve improved benefits over a simple random
 1038 approach. Indeed, we see improvements of 22% with perfect
 1039 knowledge and 21% using our BF based prediction com-
 1040 pared to a random allocation policy. We also observe a sig-
 1041 nificant difference between the statistical and analytical pre-
 1042 diction schemes. The regression approach is unable to scale
 1043 in terms of accuracy with increased heterogeneity, whereas
 1044 the BF approach achieves close to optimal power savings.

1045 In order to evaluate how well our allocator can exploit
 1046 DPM support, we extend the thirteen platform type configu-
 1047 ration with an additional Woodcrest 3 GHz platform which
 1048 provides DPM support. We again find that our BF prediction
 1049 method can provide improved aggregate savings across all
 1050 machines over the statistical approach as shown in Fig. 7(b).
 1051 To more closely determine our ability to exploit DPM mech-
 1052 anisms, we also evaluate the power consumption of the thou-
 1053 sand DPM-enabled platforms (all of which are active). We
 1054 find that our BF model based allocation is able to improve
 1055 the power efficiency of these platforms by 3.3%. This illus-
 1056 trates the potential of HALM to provide additional benefits
 1057 when platforms vary in the power management they support.

1059 7.2 Maximizing performance under power budgets 1060

1061 As a second benefit of HALM, we evaluate the ability to
 1062 perform load shedding when power budgeting must be per-
 1063 formed. In particular, our goal is to maximize performance
 1064 obtained in the data center while observing power budgets.
 1065 For the purposes of this paper, we consider transient power
 1066

1025 Fig. 7 HALM power improvements

Cluster Comput

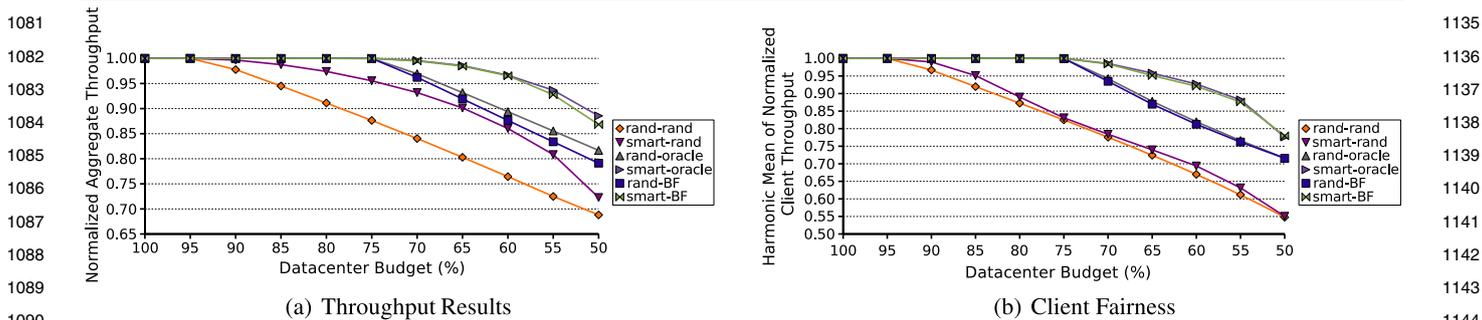

Fig. 8 Power budgeting results

budgeting where workloads are not (re-)migrated, but instead, based upon an existing allocation, resources are temporarily withheld from applications and placed into low power states. For comparison, we consider three such initial allocations from the previous section, one based upon a random allocation, one based upon perfect oracle performance information, and finally an allocation based upon prediction with our BF approach. For each allocation, we consider two load shedding policies, one which randomly selects an application and sheds resources (i.e. a single compute node) if possible, and our greedy “smart” policy described in Sect. 6.2.

Figure 8(a) provides the aggregate performance across all workloads in the data center for different power budgets. The performance results are normalized with respect to the maximum achievable performance at the maximum unconstrained power budget (100%). The figure shows how the performance of different allocation policies decrease with decreasing power budgets. The range of applied power budgets is limited to 50% as there is no possible allocation that meets the budget below this point. The six scenarios considered are random shedding based upon a random allocation (rand-rand), our load shedding policy based upon a random allocation (smart-rand), similarly the two shedding approaches based upon oracle based allocation (rand-oracle and smart-oracle), and finally, shedding based upon a BF prediction based allocation (rand-BF and smart-BF). We see multiple interesting trends. First, the intrinsic benefits of the heterogeneity-aware allocations towards budgeting are apparent in the figure by the fact that performance does not begin to reduce until lower power budgets compared to a random allocation scheme. We also see that given a particular allocation, our shedding policy provides benefits in performance across the set of power budgets. Moreover, again, we find that our BF prediction model behaves very close to an oracle based allocation when our load shedding policy is used. Overall, we see benefits of up to 18% in performance degradation compared to a random load shedding policy based upon a random allocation. Figure 8(b) evaluates the performance degradations for the six approaches by also

taking the fairness of load shedding into account. Here, we show the aggregate data center performance as the harmonic mean of the individual workload throughputs, which is a commonly used metric for evaluating fairness [20]. We see from the figure that a random allocation always exhibits poor performance regardless of the load shedding policy used. A heterogeneity-aware allocation, on the other hand, provides improved fairness, particularly when combined with our load shedding policy.

8 Related work

HALM builds upon existing work and extends the state of the art in power management research. A variety of mechanisms exist to provide power and thermal management support within a single platform. Brooks and Martonosi proposed mechanisms for the enforcement of thermal thresholds on the processor [3], focusing on single platform characteristics as opposed to the data center level management achieved with HALM. Processor frequency and voltage scaling based upon memory access behavior has been shown to successfully provide power savings with minimal impact to applications. Resulting solutions include hardware based approaches [19] and OS-level techniques, that set processor modes based on predicted application behavior [14]. HALM is designed to manage load while being aware of such underlying power management occurring in server platforms. Power budgeting of SMP systems with a performance loss minimization objective has also been implemented via CPU throttling [16]. Other budgeting solutions extend platform support for fine grain server power limiting [18]. The power budgeting achieved with HALM is based upon the use of resource allocation to reduce power consumption across multiple systems, as opposed to throttling performance of individual components.

At the data center level, incorporating temperature-awareness into workload placement has been proposed by Moore et al. [21], along with emulation environments for studies of thermal implications of power management [11]. HALM can use these thermal aware strategies to perform

1189 power budgeting based upon data center temperature character- 1243
 1190 istics. Chase et al. discuss how to reduce power consump- 1244
 1191 tion in data centers by turning servers on and off based on 1245
 1192 demand [4]. Utilizing this type of cluster reconfiguration in 1246
 1193 conjunction with DVFS [7] and the use of spare servers [23] 1247
 1194 has been investigated as well. As opposed to these ap- 1248
 1195 proaches, HALM attempts to reduce power consumption 1249
 1196 by intelligently managing workloads across heterogeneous 1250
 1197 servers. Enforcing power budgets within data centers by al- 1251
 1198 locating power in a non-uniform manner across nodes has 1252
 1199 been shown to be an effective management technique [9]. 1253
 1200 Techniques for enforcing power budgets at blade enclosure 1254
 1201 granularities have also been discussed [24]. HALM bud- 1255
 1202 gets aggregate power consumption via resource allocation 1256
 1203 without assigning per server power budgets as with these 1257
 1204 previous approaches. 1258

1205 Heterogeneity has been considered to some degree in 1259
 1206 prior work, including the evaluation of heterogeneous multi- 1260
 1207 core architectures with different core complexities [17]. In 1261
 1208 comparison, HALM considers platform level heterogene- 1262
 1209 ity as opposed to processor asymmetry. In cluster environ- 1263
 1210 nments, a scheduling approach for power control has been 1264
 1211 proposed for processors with varying fixed frequencies and 1265
 1212 voltages [10]. HALM supports heterogeneity across addi- 1266
 1213 tional dimensions, such as power management capabilities 1267
 1214 and memory. A power efficient web server with intelligent 1268
 1215 request distribution in heterogeneous clusters is another ex- 1269
 1216 ample which considers leveraging heterogeneity in enter- 1270
 1217 prise systems [12]. HALM goes beyond these methods, by 1271
 1218 considering not just the differences in platforms' perfor- 1272
 1219 mance capabilities, but also in their power management ca- 1273
 1220 pabilities. 1274

1222 **9 Conclusions and future work**

1224
 1225 Power management in data center environments has become 1275
 1226 an important area of research, in part because power delivery 1276
 1227 and cooling limitations are quickly becoming a bottleneck 1277
 1228 in the provisioning of performance required by increasingly 1278
 1229 demanding applications. This paper makes use of the man- 1279
 1230 agement flexibility afforded by virtualization solutions to 1280
 1231 develop a heterogeneity-aware load management (HALM) 1281
 1232 system. HALM improves power management capabilities 1282
 1233 by exploiting the natural heterogeneity of platforms in data 1283
 1234 centers, including differences in dynamic power manage- 1284
 1235 ment support that may be available. We introduce a three 1285
 1236 phase approach to mapping workloads to underlying re- 1286
 1237 sources to improve power efficiency consisting of struc- 1287
 1238 tured platform and workload descriptors, a prediction com- 1288
 1239 ponent to estimate the performance and power characteris- 1289
 1240 tics of various workload to platform mappings, and finally 1290
 1241 an allocator which utilizes policies and prediction results to 1291
 1242 1292

perform decisions. We also evaluate a load shedding pol-
 icy based upon resulting allocations to improve performance
 when power budgeting must be performed.

Our results underscore two major conclusions. First, we show that by intelligently considering the varying power management capabilities of platforms, the ability for these systems to obtain power savings using their management mechanisms can be vastly improved when compared to other assignment models. Using representative data center configurations consisting of older P4 based platforms up to Intel Core microarchitecture based systems, we find that our allocation architecture can improve power efficiency by 20% on average. In addition, our results show that by performing intelligent load shedding when power budgets must be observed, 18% improvements in performance degradation can be obtained when using HALM.

In this paper, we present the beginning of our investigation into exploiting platform heterogeneity and emerging virtualization support to improve the power characteristics of enterprise computing environments. As future work, we plan to integrate the management tradeoffs and lessons learned from this work into virtualization layer management applications. This includes the consideration of distributed virtualized workloads such as tiered web services where different components may be appropriate for each layer, including heterogeneous I/O devices. The results presented in this paper support the potential of this area of research for power managing heterogeneous computing systems.
